Abstract: Mysid crustaceans are frequently used in the laboratory to feed cephalopods and fish, but not along the Pacific coast, where they are scarce. There is no commercial aquaculture of mysids in the Pacific Ocean. To change this situation, we calculate fecundity, survival, and sex ratio of *Mysidopsis californica* under semi-controlled conditions. Mysids were collected manually using a 500 μm -mesh net along the rocky coast of Mazatlán, Sinaloa, Mexico. They were transferred to three 30 L seawater aquaria in the laboratory, and fed (*ad libitum*) *Artemia* nauplii and rotifers. Two generations were obtained. The relationship between the number of juveniles born and parent female lengths showed a rate of 1.56 juveniles released per each unit of increasing parent female length. An average parent female length of 6.92 mm (SD=0.82) gave 9.96 (SD=4.29) released juveniles. The frequency of female length showed a mean of 7.3 mm (SD=0.54), whereas that of juveniles showed a mean of 1.7 mm (SD=0.16). Survival and sex ratios (females-males) varied from 77.7 % to 88.6 % and 2.5:1 to 3.0:1, respectively. Rev. Biol. Trop. 56 (2): 535-539. Epub 2008 June 30.

Key words: *Mysidopsis californica* (Mysida, Mysidae), fecundity, survival, sex ratio, Mexican Pacific Ocean.

A distinguishing characteristic of mysids is their broad pouch or ventral marsupium in mature females, where the embryos develop directly into juveniles, possessing many adult characters. Wortham-Neal and Price (2001) studied the marsupial developmental stages in *Americamysis bahia* (Mysida: Mysidae and Lophogastridae). Most shallow waters mysids measure between 2 and 30 mm in length, but some bathypelagic species such as *Gnathophausia*, grow up to 35 cm. Most mysids are omnivorous.

In the natural environment, mysids often congregate in large groups and constitute the diet of many large marine organisms (Ruppert and Barnes 1996). Hence, mysids are frequently used in the laboratory to feed juveniles of cephalopods (Clarke *et al.* 1989, Hanlon *et al.* 1991, Dominguez *et al.* 2004) as

well as fish (Woods 2005, Foster *et al.* 2001, Reicher 2003).

Mysids along the Pacific coast are scarce and as a consequence are rarely used as a food source in the laboratory. There is no commercial aquaculture of mysids in the Pacific Ocean. Therefore the purpose of this study is to estimate fecundity, frequency of reproduction, survival, and sex ratio of *Mysidopsis californica* under semi-controlled conditions, these results may help in planning mass culture of mysids for feeding some laboratory raised and maintained marine specimens.

MATERIALS AND METHODS

Mysids were collected manually using a 500 μm -mesh net in the Mazatlán Bay along

the rocky coast of Mazatlán, Sinaloa (Mexico) on February 10, 2003 and January 15, 2004. They were transferred to three 30 L seawater aquaria in the laboratory, and fed (*ad libitum*) *Artemia* nauplii and rotifers. From these, 406 brooding females were selected and placed individually in 150 ml plastic containers and fed *Artemia* nauplii. The juveniles of each female were counted and measured as they dropped from the marsupia of females. From January 15th sampling, 250 juveniles were settled in three 2 L flasks. Two generations were obtained to register the time of marsupium development and release of juveniles; from the second generation 36 juveniles were settled likewise to obtain the same parameters. Released juveniles by females were counted. Survival was also calculated. The adult's sex ratio of reproductively active mysids was also calculated in three occasions in January 15th 2004 sampling settled in the 30 L aquaria.

RESULTS

Table 1 shows that from 250 juveniles settled in three 2 L flasks on 16th february, a mature marsupium appeared between March 1 to 5 (13-17 days), then they released the brood 6-7 days later (March 13) of the first generation, the parents showed a survival rate of 88

%, at a range temperature between 20.5 and 21.2 °C, and salinity of 35 ‰. From these, 36 juveniles of the second generation were moved to other three 2 L flasks on 15th March. In these juveniles a mature marsupium appeared in about 12 days (March 27), then they released the brood in about six days (April 2), the parents showed a survival rate of 77.7 %, at a temperature range of 21.6 to 23.3 °C, and salinity of 34 ‰. An average female length of 6.96 mm (SD=0.82) released 9.96 (SD=4.29) juveniles. The females-males ratio varied from 2.5:1 to 3.0:1. They were fed with *Artemia* nauplii and rotifers (*ad libitum*).

Fig. 1 depicts the relationship between the number of released juveniles and the maternal lengths, revealing a low correlation ($r=0.27$, $p=0.1969$), which is not significant. Although relationship shows that 1.56 juveniles are released per unit of length increase. Four hundred and six female parents yielded a mean length of 7.1 mm (SD=0.54) and a mean juveniles release of 10.3 (SD=3.15). Fig. 2 depicts the length frequency histogram of females and juveniles revealing a mean of 7.3 mm (SD=0.54) and a mean of 1.7 mm (SD=0.16), respectively.

The information obtained from this study may be helpful in planning mass cultures of mysids for feeding some laboratory raised and maintained marine specimens.

Fig. 1. Relationship between females length with juveniles released. X data are from the year 2003, and O data are from the year 2004. Juveniles released = 40-4.16 (Females length) $n=406$, $r=0.27$.

TABLE 1
First and second generations of mysids born under semi-controlled conditions of temperature and salinity

1st Generation						
Initial	Flask 1 # org.	Flask 2 # org.	Flask 3 # org.	Total org.	Temperature	Salinity
16 feb 04 *	83	83	84	250	20,5	35
Final / released						
13 Mar. 04	73	74	73	220	21,2	35,1
Surviving	88%	89%	89%	88%		
2nd Generation						
Initial	Flask1 # org.	Flask2 # org.	Flask3 # org.	Total org.	Temperature	Salinity
15 March 04 **	12	12	12	36	21,6	34
Final / released						
2 Apr 04	9	9	28	23,3	34	
Surviving	75%	83,30%	75%	77,70%		

Relation females:males					
		Females	Males	Total	females:males
1 st Exp.	18 march 04	102	34	136	3.0: 1.0
2 nd Exp.	20 march 04	175	71	246	2.5: 1
3 th Exp.	22 march 04	79	30	109	2.6: 1

Mean released juveniles by females length

Females length 7.1 mm

Released juveniles 10.3

* Marsupium development march 1st - 5th

** Marsupium development march 27th

DISCUSSION

Wittmann (1984) found that temperature is an important environmental factor for marsupial development. Many species of mysids have an incubation period between eight and 180 days at temperatures between 3 °C and 23 °C,

respectively. In this study the temperature varied from 20.5 to 23.3 °C. In Mazatlán Bay the marsupium developed well, but at higher temperatures is difficult to find *M. californica*.

The number of embryos among different species varies: *Bowmaniella floridiana* yielded between 2 and 55 embryos per each

Fig. 2. Frequency of adult female's length, and juveniles length.

mature female, *Eucopia unguiculata* (*E. han-seni*) between 8 and 23 embryos (Casanova 1977), and *Metamysidopsis swifti* between 3 and 42 embryos (Clutter 1967). Mauchline (1973a, 1973b) found that brooding females of *Pranus inermis* of 13 and 15 mm length produce between 7 and 32 embryos, respectively. The same author (1973b) found also that, in 133 mysids species, the female length varied between 1.8 and 145 mm, the number of brood was between 1 and 245 and the eggs diameter was between 0.2 and 4 mm. This study shows that females between 5.5 to 8.5 mm produced between 2 to 16 juveniles; an average female length of 7 mm produced an average brood of 10 juveniles.

Mauchline (1973a) and Wittmann (1981) calculated a mortality rate of 10 % during development of embryos in the wild due to premature expulsion from the marsupium. The mortality rate included cannibalism and the effect of parasite isopods. The present study revealed a mortality rate between 12 and 23 %, at temperatures between 20.5 and 23.3 °C, respectively.

The results of this study provide data that can be useful for aquaculture of this mysid species as a food source for fish larvae and crustaceans kept in the laboratory. Regarding culture of *M. californica*, it is important to have enough live *Artemia* as food, temperatures around 20 ± 2 °C, to clean the daily debris, and to provide adequate aeration.

RESUMEN

El objetivo de este trabajo fue calcular la fecundidad, supervivencia y la proporción de sexos de *Mysidopsis californica* en condiciones semi-controladas. Los animales fueron recolectados manualmente utilizando una red con malla de 500 μm a lo largo de la costa rocosa de Mazatlán, Sinaloa, México. Una vez en el laboratorio fueron colocados en tres acuarios de 30 L cada uno y alimentados con nauplios de *Artemia* y rotíferos; estudiándose dos generaciones. La relación entre el número de jóvenes nacidos y la longitud de las madres dio una tasa de 1.56 jóvenes nacidos por cada unidad de incremento de la longitud de la hembra. En promedio, hembras de 6.92 mm (SD=0.82) producían 9.96 (SD=4.29) jóvenes. La frecuencia de la longitud promedio de la hembra fue de 7.3 mm (SD=0.54), mientras que los jóvenes medían en promedio 1.7 mm (SD=0.16). La supervivencia y la proporción de sexos (hembras-machos) varió entre 77.7 % y 88.6 % y entre 2.5:1 y 3.0:1, respectivamente.

Palabras clave: *Mysidopsis californica* (Mysida, Mysidae), fecundidad, supervivencia, proporción de sexos, Océano Pacífico Mexicano.
